Abstract

In this work, zeolite X, a benchmark adsorbent for carbon capture, has been successfully prepared from low cost waste minerals namely laterite residue and bauxite using alkali fusion process followed by hydrothermal treatment. The structure and morphology of the as-synthesized zeolite X were verified and characterized with a range of experimental techniques such as x-ray diffraction, scanning electronic microscopy and infrared spectroscopy. The surface area and (N\textsubscript{2} and CO\textsubscript{2}) gas adsorption isotherms of this product were found comparable to that of commercial ones, demonstrating the effectiveness of synthesizing zeolite X from laterite and bauxite. Further improvement of the product purity was also accomplished by optimizing the process conditions.

Key words: Zeolite X, preparation, laterite residue, bauxite, CO\textsubscript{2} capture

1. Introduction

Nickel is a strategic metal and widely used in stainless steel, batteries, fuel cells, electroplating, catalyst, and etc [1-3]. Currently, the world’s recoverable nickel resources can be divided into two main categories, respectively sulfide ores and laterite ores, depending on the geological compositions [4]. The global nickel supply has been predominantly from sulfide deposits, although laterite ores comprise approximately 70\% of the continental nickel resources [5, 6]. The reason is that the recovery process of nickel from the laterite ores is quite costly, because of the complex mineralogy and low nickel content of laterite [7]. Recently,
however, the laterite exploitation has received extensive attentions, due to the reduction of nickel sulfide reserves as well as significant increase in nickel demands [8, 9]. Therefore, there is an increasing interest in the utilization of laterite.

In general, nickel can be recovered from the laterite by using pyrometallurgical, hydrometallurgical or combined (pyro-hydrometallurgical) techniques [10, 11]. Pyrometallurgical process comprises of reduction roasting, electric furnace for ferronickel production, and rotary kiln carbon reduction, etc [12, 13]. Nevertheless, the hydrometallurgical processes consist of ammonia leaching, acid leaching, high-pressure acid leaching and bacteria leaching, etc [14, 15]. However, these processes can generate large amount of solid waste, which causes serious environmental pollution. Large volumes, approximately 40 million tons, of laterite residue are generated annually in China alone [16]. Current metallurgical processes usually focus on the recovery of Ni and/or Co, whereas laterite residue containing other waste minerals are all discarded, which brings enormous burden to the environment [17]. Therefore, converting laterite residue into useful commodity could offer a number of benefits from both economic and environmental aspects. Nevertheless, to our best knowledge, little information is available in literature on the effective utilization of the laterite residue. Laterite residue consists essentially of SiO₂, Al₂O₃ and Fe₂O₃ [3], presenting a similar composition to that of natural zeolites, which makes it possible to use laterite residue as source materials in zeolites production. Zeolite X is one of the zeolites that have been widely used in adsorption, separation, ion exchange and catalysis, due to its large surface areas, molecular sieving ability and acidity [18, 19]. Particularly, zeolite X is also a well-known adsorbent for CO₂ capture from flue gas streams owing to its high selectivity of CO₂ against N₂ [20, 21]. In this paper, we report the synthesis of zeolite X using laterite residue as raw materials, in which another common mineral bauxite was added to the starting material to maintain an appropriate Si/Al ratio during the hydrothermal
treatment, because otherwise the large ratio of Si/Al in the laterite residue would inhabit the formation of zeolite X during the hydrothermal reactions.

The ultimate aim of this work was to develop a new route to utilize the laterite residue for the production of zeolites that can be used for CO$_2$ capture from flue gas streams. To obtain high purity of zeolite X, the molar ratios of the components in the starting materials and during the hydrothermal treatment should be carefully controlled. The optimum synthesis procedure was established in this study, and the carbon capture potential of our as synthesized products was also investigated.

2. Experimental

2.1 Synthesis

Laterite residue and bauxite was obtained from Sichuan Province (China) and Indonesia, respectively. The chemical compositions of laterite residue, bauxite and prepared zeolite X were analyzed by XRF (ZSX100e, Rigaku) and described in Table 1 showing 39.1wt.% Si and 1.2wt% Al in laterite residue and 8.7wt.% Si and 31.5wt.% Al in bauxite. For comparison purposes, commercial zeolite X beads were also purchased from Sinopharm Chemical Reagent Co., Ltd.

The synthesis procedure for zeolite X is summarized schematically in the flow diagram Fig. 1, which involved two steps viz. fusion and hydrothermal treatment. In a typical procedure, 5 g of laterite residue was mixed with bauxite using different molar ratios of SiO$_2$/Al$_2$O$_3$ mole ratios such as 3, 3.2, 3.5, and 3.8. Then, NaOH was added into the resulting mixture to adjust the Na$_2$O/SiO$_2$ mole ratio to a desired value in the range of 1.4-2.6. The mixture was fused in a tube furnace at 600 °C for 2 h. Then, the resulting product was dissolved in water with various H$_2$O/Na$_2$O ratio (35, 40, 43, 48, 55, and 60 mol•mol$^{-1}$), followed by ageing of different time (0, 8, 12, 24, and 48 h). The mixture was transferred into an autoclave and heated at 100 °C for different hydrothermal reaction time (0.5, 3, 6, 12, and 24 h) under static
conditions. After cooling to the room temperature, the resultant solid was filtered, washed three times with deionized water, and dried at 100 °C overnight. The synthesis conditions used with different samples are presented in Table 2 (Group A-E). Note that the optimal synthesis conditions determined from the experiments of Group A was carried on to the experiments of Group B, likewise finally to group E.

2.2 Measurement and characterization

The crystalline properties of the raw materials and the synthesized samples were examined by X-ray diffraction (XRD) using a Shimadzu X-ray diffractometer, with a scanning rate of 2°/min from 4° to 50°. FE-SEM (Field Emission Scanning Electron Microscopy) analysis was conducted by employing a Hitachi S-3400N scanning electron microscope operated at 15 kV. All samples were platinum coated prior to measurement. BET surface areas were measured on an ASAP2020 analyzer (Micromeritics, USA) using N2 as probe gases at 77 K in the relative pressure range of 0.05-0.25. CO2 and N2 adsorption isotherms were measured on ASAP2020. Prior to analysis, all the samples were degassed under vacuum at 330 °C for 8 h. Infrared spectroscopy was performed using an Agilent Cary 600 FTIR instrument, and samples were mixed with KBr using a mortar before the measurement.

3. Results and discussion

3.1 Raw materials characterization

The X-ray diffraction pattern of laterite residue (Fig. 2) indicates that the crystalline phases are mainly SiO2, Mg3Si2O5(OH)4, Mg3Si4O10(OH)2, and Mg1.8Fe0.2[SiO4], identified by their characteristic sharp peaks at the corresponding positions. The X-ray diffraction pattern for bauxite (Fig. 3) indicates the major crystalline phase is gibbsite, with coexistence of anatase, α-quartz, kaolinite, and hematite [22].

The chemical compositions of the raw materials (Table 2) by XRF show that they are impure in nature. The Si/Al ratio of the laterite residue and bauxite are about 29.034 and
0.248, respectively, indicating that laterite residue and bauxite are rich in silica and alumina, respectively, a favorable combination as raw materials for synthesizing zeolite X. Furthermore, XRF data reveals that the raw materials contain a very small amount of impurity, which suggests high purity of zeolites X could be obtained using laterite residue and bauxite.

3.2 Zeolite X synthesis and characterizations

3.2.1 Effect of Na$_2$O/SiO$_2$ mole ratios

The effect of Na$_2$O/SiO$_2$ mole ratios on zeolite X formation was determined by mixing NaOH, laterite residue and bauxite at the Na$_2$O/SiO$_2$ ratio range of 1.4 to 2.6 at 600°C for 2 h. The XRD spectra of the zeolite products obtained at different Na$_2$O/SiO$_2$ ratio were shown in Fig.3 (A1-A6). At the Na$_2$O/SiO$_2$ ratio of 1.4, strong peaks of zeolite X along with weak ones of zeolite P were observed, suggesting a minor contamination by zeolite P byproduct. When a Na$_2$O/SiO$_2$ ratio of 1.6 was used as the synthesis condition, the peaks of zeolite P disappeared, indicating any latent zeolite P was transformed into zeolite X completely during the hydrothermal reaction. When the Na$_2$O/SiO$_2$ ratio was increased to 1.8 or higher, a large fraction of zeolite P contaminant was found in the product, while at the ratio of 2.6, a secondary contaminant sodalite was observed in addition to zeolite P. According to the XRD results of products in Group A, the optimal Na$_2$O/SiO$_2$ ratio for attaining high purity zeolite X (product A2) is 1.6, and this optimal ratio was used throughout the entire experiments.

3.2.2 Effect of SiO$_2$/Al$_2$O$_3$ mole ratios

Adjusting SiO$_2$/Al$_2$O$_3$ ratio of the starting materials prior to hydrothermal reaction is an important aspect to obtain pure zeolites. Fig. 4 shows the X-ray diffraction patterns for products prepared at the ratio range from 3 to 3.8. The XRD results show that zeolite X was the main phase at this ratio range. The SiO$_2$/Al$_2$O$_3$ ratio of 3.2 was a critical ratio to synthesize pure zeolite X. At the ratio of 3, zeolite X and amorphous impurity phase were
obtained. However, when SiO$_2$/Al$_2$O$_3$ increased to 3.5 or higher, the peaks of zeolite P also appeared, indicating that a higher ratio of SiO$_2$/Al$_2$O$_3$ results in the formation of zeolite P. These findings show that SiO$_2$/Al$_2$O$_3$ ratio is a key factor for the preparation of different types of zeolites, which is in good agreement with earlier report [23]. Thus, the optimum SiO$_2$/Al$_2$O$_3$ ratio was 3.2, wherein high purity zeolite X was obtained. Therefore, this ratio was used in the following study.

3.2.3 Effect of H$_2$O/Na$_2$O mole ratios

Crystallization of zeolites occurs through nucleation and crystal growth, depending a lot on alkalinity. The effect of H$_2$O/Na$_2$O mole ratios of the starting materials, in the range of 35 to 60, was investigated by XRD examination on the corresponding samples, and the results were shown in Fig.5. The XRD analysis showed that crystallinity of synthesized zeolite decreases with increase in H$_2$O/Na$_2$O ratio. Zeolites could be obtained when the H$_2$O/Na$_2$O ratios were less than 55. At a H$_2$O/Na$_2$O ratio of 35, the peaks of sodalite appeared indicating sodalite was the main phase. When the H$_2$O/Na$_2$O ratio increased to 40, pure zeolite X was obtained indicating the transformation of sodalite into zeolite X. When H$_2$O/Na$_2$O mole ratio further increased to 43, the peaks of zeolite P appeared, suggesting a high H$_2$O/Na$_2$O mole ratio could induce the formation of zeolite P. However, XRD patterns of the sample at the H$_2$O/Na$_2$O mole ratio of 55 clearly show broad amorphous peaks combined with quartz and small peaks of zeolite X indicating only a few zeolite X particles were nucleated. This reveals that higher H$_2$O/Na$_2$O ratios may inhibit the formation of zeolite X from laterite residue and bauxite, probably because low alkalinity reduces dissolution of silicate and leads to a poor conversion to zeolites. The best zeolite X was obtained from the starting materials with H$_2$O/Na$_2$O mole ratio of 40, and thus, this H$_2$O/Na$_2$O ratio was able to be used in the following experiments.

3.2.4 Effect of aging time

6
Aging is also an important factor for the zeolite synthesis process. In order to investigate the influence of aging time on zeolite X preparation, time-dependent synthesis was carried out and the purity of the products was examined by XRD analysis (Fig.6). Extended aging time from 0 h to 24 h can improve the purity of the product zeolite X. In particular, pure zeolite X with high crystallinity could be obtained at the aging time of 24 h. However, further prolonging the aging time to 48 h, zeolite X was again heavily contaminated with zeolite P impurity. It suggests that aging time plays a significant role in the formation of zeolites prepared from laterite residue and bauxite. Thus, an optimal aging time of 24 h was determined for obtaining high purity zeolite X, and the aging time of 24 h was used through the rest of the study.

3.2.5 Effect of hydrothermal reaction time

XRD patterns of the products obtained at different reaction time were shown in Fig.7. In the first 0.5 h, the XRD pattern of the product exhibits a very broad peak located around at 27° in 2θ, combined with some small peaks of zeolite X, suggesting the formation of amorphous aluminosilicate and a small amount of zeolite X. However, the evolution from amorphous phase into zeolite X occurred in a short time period. Zeolite X with very low impurities of amorphous phase was produced, by extending to 3 h of reaction time. Further increasing reaction time to 6 h, highly crystalline and pure zeolite X was obtained. When the reaction time was lengthened to 12 h, pure phase of zeolite X was still observed. Nevertheless, longer time crystallization also caused the transformation of zeolite X into sodalite. At the crystallization time of 24 h, the diffraction pattern of zeolite sodalite appeared. This is probably because sodalite is more thermodynamically stable than zeolite X, and longer reaction time favors the formation of more stable sodalite type zeolite. Therefore, a reaction time of 6 h is sufficient for the formation of high purity zeolite X.

According to the experiments above, the optimal synthesis conditions for zeolite X were
found as follows: H2O:Na2O:SiO2:Al2O3 ratio of 204.8:5.12:3.2:1, and the product obtained at the optimal conditions was used in the following experiments.

3.3 Morphological and structural analysis

The morphologies of the laterite residue, bauxite and zeolite X were presented in Fig. 8. SEM images for laterite residue and bauxite (Fig. 8a, b) show particles with a wide size distribution and irregular shape. Figure (8c-d) show the low and high resolution SEM micrographs of as-synthesized zeolite X with typical octahedral structure and uniform distribution. In addition, amorphous material was hardly noticeable in the SEM images of as-synthesized zeolite X, suggesting the formation of highly crystalline zeolite X. Furthermore, the XRF results show that the prepared zeolite X consists of Na, Al, Si, Fe, Mg, with a wt. % of 9.9, 14.6, 23.9, 2.6, and 1.2, respectively, and the molar ratio of Na/Al/Si falls in the region of theoretical formula of pure zeolite X, which means most of the trace impurities were removed during the fusion and hydrothermal reaction process. The N2 adsorption isotherm at 77K and pore size distribution of prepared zeolite X are shown in Fig. 9. BET surface area of as-synthesized zeolite X was around 486 m²/g, a little smaller than that of the commercial one (596 m²/g), which may be attributed to the small fraction of impurities. Furthermore, the pore size of as-synthesized product was approximately 7 Å. All these findings suggest that high purity zeolite X was obtained at the optimum reaction conditions.

FT-IR spectra can be useful in obtaining crucial information about the structure of zeolites. Fig. 10 presents the spectra of commercial zeolite X and the as-synthesized one. It can be seen that our synthesized zeolite X has almost identical spectra to the commercial one. All these observations further confirm successful preparation of high purity zeolite X.

3.4 Adsorption Properties

The representative adsorption isotherms measured at 0 °C and 30 °C for pure CO2 and N2 on the prepared zeolite X were shown in Fig. 11. The adsorption loadings of CO2 and N2 on
prepared zeolite X are well comparable to that of the commercial one [18]. Furthermore, the prepared zeolite X is very selective to carbon dioxide at 0 °C and 30 °C through the whole pressure range, and the equimolar selectivities of CO2/N2 were shown in Fig.12. For example, in the partial pressure region of 5-15 kPa (for individual component), the equilibrium adsorption capacity of CO2 is about 60-115 times higher than those for N2 at 30 °C, suggesting zeolite X prepared from laterite residue and bauxite can be a very good adsorbent for postcombustion carbon capture by vacuum swing adsorption where the partial pressure of CO2 in the flue gases is around 10 kPa only [24, 25]. In addition, it may also be used for CO2 removal in the process of air purification [26].

The adsorption isotherms of CO2 and N2 on our zeolite X material were fit by classical Langmuir equations:

\[
N = \sum_{i} \frac{M_i B_i P}{1 + B_i P} \quad (1)
\]

\[
B_i = b_i \exp \left( \frac{Q_i}{RT} \right) \quad (2)
\]

where \(N\) is the adsorbed amount (mol·kg\(^{-1}\)), \(M_i\) the maximum monolayer adsorption capacity for site \(i\), \(b_i\) the gas-solid affinity coefficient (kPa\(^{-1}\)), \(Q_i\) the enthalpy of adsorption (J·mol\(^{-1}\)), \(P\) the pressure (kPa), \(R\) the gas constant (J·mol\(^{-1}\)·K\(^{-1}\)) and \(T\) the temperature (K). \(N\), \(P\) and \(T\) are variables. We used a dual sites model for CO2 (i.e. \(i = 2\)) to characterize its surface heterogeneity and a single site model for N2 adsorption (\(i = 1\)). The results of the fitted parameters are shown in Table 3 with a very high goodness of fitting. The enthalpy of adsorption values derived from our model are in very close match of that reported in literature [25]. We further calculated the isosteric heat of adsorption by applying the Clausius-Clapeyron equation with the Langmuir model parameters we obtained. As shown in Fig. 13, CO2 has a much higher heat of adsorption than that of N2, with a difference from 12.2 kJ/mol at low surface coverage to 11 kJ/mol at high coverage, which is responsible for the high
selectivity of CO$_2$ over N$_2$ on our synthesized zeolite X. These information will complement the design and simulation of vacuum or pressure swing adsorption (VSA/PSA) processes while applying our adsorbents.

4. Conclusion

Laterite residue and bauxite have been successfully utilized for the production of zeolite X for the first time. The optimal synthesis conditions for zeolite X were found as follows: H$_2$O:Na$_2$O:SiO$_2$:Al$_2$O$_3$ ratio of 204.8:5.12:3.2:1; aging time of 24 h, and hydrothermal reaction time of 6 h. SEM images of as-synthesized zeolite X particles exhibit typical octahedral morphology with uniform size distribution. The prepared zeolite X shows similar surface areas to that of commercial ones. Furthermore, the adsorption properties of our prepared X are comparable to the commercial ones in terms of CO$_2$ and N$_2$ adsorption equilibrium capacities. This study may bring a new and alternative approach for large scale recycling of laterite residue wastes for making valuable zeolite X that are highly in demand for adsorption based carbon capture processes.

Fig. 7. XRD patterns of zeolites synthesized at the crystalline time of (E1) 0.5 h, (E2) 3 h, (E3) 6 h, (E4) 12 h, (E5) 24 h, where X represents zeolite X, S represents zeolite sodalite and Q corresponds to quartz impurity.
Fig. 8. SEM images for: (a) laterite residue, (b) bauxite, (c, d) as-synthesized zeolite X at high and low magnifications respectively.
Fig. 9. (a) N$_2$ adsorption isotherm, and (b) pore size distribution of prepared zeolite 13X.
Fig. 10. FTIR spectra of commercial and as-synthesized zeolite X.
Fig. 11. Adsorption (filled) and desorption (hollow) isotherms of CO$_2$/N$_2$ on zeolite X at 0 °C and 30 °C.
Fig. 12. Equimolar selectivities of CO$_2$/N$_2$ on zeolite X at 0 °C and 30 °C.
Fig. 13. Calculated isosteric heat of adsorption of CO₂ and N₂ on zeolite X at 0 °C.
