### Highlights

- We demonstrate reference electrode free AlGaN/GaN transistor-based  $\text{Ca}^{2+}$  sensors.
- Lower detection limit  $10^{-8}$  M and linear response range  $10^{-7}$ - $10^{-2}$  M in KCl and NaCl.
- Lowest reported detection limit for reference electrode free  $\text{Ca}^{2+}$  sensors.
- Improved detection limits compared to ISEs in classical setup and previous ISFETs.
- These findings are critical for *in situ* applications of calcium ion sensing.

# Ca<sup>2+</sup> detection utilising AlGa<sub>N</sub>/Ga<sub>N</sub> transistors with ion-selective polymer membranes

## Abstract

We demonstrate highly selective and sensitive potentiometric ion sensors for calcium ion detection, operated without the use of a reference electrode. The sensors consist of AlGa<sub>N</sub>/Ga<sub>N</sub> heterostructure-based transistor devices with chemical functionalisation of the gate area using poly (vinylchloride)-based (PVC) membranes having high selectivity towards calcium ions, Ca<sup>2+</sup>. The sensors exhibited stable and rapid responses when introduced to various concentrations of Ca<sup>2+</sup>. In both 0.01 M KCl and 0.01 M NaCl ionic strength buffer solutions, the sensors exhibited near Nernstian responses with detection limits of less than 10<sup>-7</sup> M, and a linear response range between 10<sup>-7</sup> - 10<sup>-2</sup> M. Also, detection limits of less than 10<sup>-6</sup> M were achieved for the sensors in both 0.01 M MgCl<sub>2</sub> and 0.01 M LiCl buffer solutions. AlGa<sub>N</sub>/Ga<sub>N</sub>-based devices for Ca<sup>2+</sup> detection demonstrate excellent selectivity and response range for a wide variety of applications. This work represents an important step towards multi-ion sensing using arrays of ion-selective field effect transistor (ISFET) devices.

**Keywords:** AlGaIn/GaN; chemical sensor; calcium detection; ion selective field effect transistor

**Introduction:**

The detection of calcium ions,  $\text{Ca}^{2+}$ , is important in a wide range of applications. Calcium is essential for many biological functions such as neural and intracellular signalling, biomineralisation (bone, teeth), muscle action, and many enzymatic processes [1-3]. Monitoring calcium ion concentration in blood is important as deficiencies can lead to conditions such as muscle and nerve tightening [4] and osteoporosis. Water hardness can cause numerous problems in industrial processes and households, with dissolved calcium salts being the primary reason for scaling in pipes and water heaters. Further applications, where the detection of calcium ions can be crucial, include food processing [4], chemical oceanography [5] and agriculture [6, 7].

Atomic absorption spectrometry (AAS) is a traditional method often used for quantifying calcium content. However, sample preparation for AAS is tedious (acid digestion). Furthermore, AAS is often expensive, bulky and not suitable for in situ real-time monitoring. In contrast, ion selective electrodes (ISEs) have the advantages of better portability, lower cost, and excellent selectivity [8]. Furthermore, ISEs can be used for the detection of calcium in its biologically active form,  $\text{Ca}^{2+}$  [9]. Ion selective field effect transistors (ISFETs) have further advantages over traditional ISEs, such as higher signal-to-noise ratios, faster response times, and the potential for further miniaturization and integration into systems [10].

ISEs with poly(vinyl chloride) (PVC) based membranes, for the detection of  $\text{Ca}^{2+}$  ions, have demonstrated detection limits down to  $5.0 \times 10^{-7}$  M, linear response ranges between  $8.0 \times 10^{-7}$ - $1.0 \times 10^{-1}$  M, and stable performance over the pH range of 3.0-11.0

[10]. Similar studies using ISFETs for calcium ion detection have also reported comparable results with lower detection limits of  $10^{-6}$  M and sensor lifetimes of up to 6 weeks [11]. The detection limits of  $\text{Ca}^{2+}$  selective ISFETs can be improved by conditioning the device in solutions containing only interfering ions to achieve zero-current ion flux for subsequent quantification of analyte solutions [12]. The type of plasticisers used in the membrane matrix can also affect the detection limit for sensors. For example, the use of *o*-nitrophenyloctyl ether (*o*-NPOE) instead of (2-ethylhexyl)sebacate (DOS) can enable detection at much lower concentrations of the analyte of interest [13]. The membranes typically consist of a polymer, a plasticiser, and neutral ion carriers (ionophores) which exhibit strong and selective binding for specific ions. Calcium ionophore ETH 1001 (or ((-)-(R,R)-N,N-Bis-[11-(ethoxycarbonyl)undecyl]-N,N',4,5-tetramethyl-3,6-dioxaoctane-diamide)) is one of these and has been widely used in clinical and biological settings for  $\text{Ca}^{2+}$  activity measurement [14, 15]. A solid-state calcium selective electrode using a poly(pyrrole) conducting polymer has the lowest reported detection limit ( $2.5 \times 10^{-10}$  M) with linear response between  $10^{-9}$ - $10^{-4}$  M [16]. However, this device, like most ISEs and ISFETs, required a bulky, fragile, and a maintenance-intensive reference electrode with inner filling solution, which hinders long-term *in situ* operation.

Despite significant advances in ISEs and ISFETs, a stable reference electrode required for the long-term operation of these sensors remains elusive. Liquid junction electrodes, such as Ag/AgCl electrodes, are commonly used as reference electrodes, but suffer from electrode solution leakage that compromises the accuracy and lifetime of the sensor [17]. To date, the best results reported for a sensor operating without a reference electrode are for an ion-selective

conductometric microsensor that showed a lower detection limit of  $10^{-7}$  M, and a dynamic range of  $10^{-6}$ - $10^{-1}$  M [9].

ISFETs based on AlGa<sub>0.3</sub>N/GaN high electron mobility transistor (HEMT) devices present a compelling alternative to conventional Si-based ISFETs, with advantages such as greater chemical stability, higher device transconductance and diminished charging effects [18, 19]. The high transconductance is the result of a 2-dimensional electron gas layer (2DEG) that forms at the AlGa<sub>0.3</sub>N/GaN interface [20]. Charges on the surface strongly influence the conductivity of the 2DEG layer, thus creating the foundation of a highly sensitive ion sensor [18, 19]. Furthermore, due to their high gain and normally-on channel, AlGa<sub>0.3</sub>N/GaN HEMT devices do not require a reference electrode, which eliminates the associated issues of instability, bulkiness, short lifetime and drift. Previous studies have showed that AlN/GaN HEMT-based sensors can successfully measure pH in solution without the need for a reference electrode [21]. Further it has previously been demonstrated that AlGa<sub>0.3</sub>N/GaN devices coated with appropriate functionalisation layers can detect NO<sub>3</sub><sup>-</sup>, PO<sub>4</sub><sup>3-</sup> and Hg<sup>2+</sup> in solution, also without the need of a reference electrode [22-25].

We have previously reported on Ca<sup>2+</sup> detection via biological mechanisms using live cells for functionalisation [26]. In this work, we report the performance of AlGa<sub>0.3</sub>N/GaN HEMT devices functionalised by ion selective PVC-based membranes for Ca<sup>2+</sup> detection. Performance characteristics of these devices such as optimal dynamic range, Nernstian slope, response time and the selectivity coefficients for a variety of interfering ions were determined.

## **Experimental:**

### *Chemical materials*

1 Calcium ionophore IV / ETH 5234 (or *N,N*-Dicyclohexyl-*N',N'*-dioctadecyl-3-  
2 oxapentanediamide), potassium tetrakis(4-chlorophenyl)borate, 2-nitrophenyl octyl  
3 ether and high molecular weight poly(vinyl chloride) were purchased from Sigma-  
4 Aldrich and used without further purification.  
5  
6  
7  
8

### 9 *Calcium selective membrane*

10 We used the optimised formulation suggested by Gehrig et al. [27] which is 10 mg of  
11 calcium ionophore IV, 2.8 mg potassium tetrakis(4-chlorophenyl)borate, 658 mg of 2-  
12 nitrophenyl octyl ether and 329 mg of high molecular weight poly(vinyl chloride) for  
13 dissolved in 30 mL THF. A solution micro-deposition system (Vermet MDV 3200)  
14 was used to deposit a uniform layer of this material (approximately 10 $\mu$ m thick) onto  
15 the active area of the sensor. The sensor was then placed in a vacuum chamber  
16 overnight to remove the solvent (THF) and enhance the adhesion of the polymeric  
17 membrane to the GaN cap layer.

### 31 *Device construction and operation*

32 Figure 1 schematically represents the sensors at various stages of fabrication and  
33 packaging, prior to functionalisation by membrane deposition. The HEMT structure  
34 consists of an MOCVD-grown AlGa<sub>N</sub>/Ga<sub>N</sub> structure ( $x_{Al} = 0.25$ ;  $d_{AlGaN} = 15.5$  nm)  
35 grown on a sapphire substrate. A Ga<sub>N</sub> cap layer of 2 nm was also grown to improve  
36 the electrochemical stability of the device (Figure 1a). Hall effect measurements  
37 showed a carrier concentration and mobility of the HEMT sample to be  $8.257 \times 10^{12}$   
38  $\text{cm}^{-2}$  and  $1472 \text{ cm}^2/\text{Vs}$ , respectively. During fabrication the wafer was first cleaned  
39 with Technistrip (sonicating for 5 min), then rinsed with isopropanol and DI water.  
40 The wafer was then dipped into a solution of aqua regia ( $\text{HNO}_3:\text{HCl}=1:3$ ) for 3 min,  
41 rinsed with DI water and blown dry with nitrogen followed by a hotplate bake for 5  
42 min at  $110^\circ\text{C}$ . Standard photolithography was used for all mask patterning. Mesa

1 isolation was achieved using inductively coupled plasma reactive ion etching with  
2  $\text{Cl}_2/\text{Ar}$  (see Figure 1b). The contact pads were formed by thermal evaporation of Al  
3 (200 nm), Cr (600 nm) and Au (300 nm) followed by lift-off (see Figure 1c). Rapid  
4 thermal annealing (RTA) was used to diffuse the Al through the GaN and AlGaN  
5 layers connecting (as shown in Figure 1d) the electrical contacts with the 2DEG layer  
6 at the AlGaN/GaN interface. For this step the sample was exposed to 1000 sccm  $\text{N}_2$   
7 in the RTA chamber at 820°C for 30 s. For device passivation, a thick layer of SU-8  
8 (10 $\mu\text{m}$ ) was deposited using spin-coating, and patterned using photolithography  
9 exposing only the active sensing area on the GaN cap layer (Figure 1e). Individual  
10 devices were then diced and mounted onto a pre-fabricated printed circuit board  
11 (PCB) with four electrode contacts (see Figure 1f). Conductive epoxy was used to  
12 form the connections between sensor electrodes and contacts on the PCB.

After depositing the calcium sensitive membrane onto the active area of the sensor, the membrane was conditioned by immersing the device in  $10^{-2}$  M  $\text{CaCl}_2$  solution for 4 hours. The device was then removed and thoroughly rinsed with deionised water for 20 minutes. The device was then equilibrated for approximately 30 min in an ionic buffer solution of KCl without any  $\text{Ca}^{2+}$  ions. Following this initial conditioning, the device was thoroughly rinsed and soaked in de-ionised water for 20 min. For testing, the device was exposed to solutions of different interfering ions (0.01 M KCl, 0.01 M NaCl, 0.01 M  $\text{MgCl}_2$  and 0.01 M LiCl) until a stable baseline was achieved (about 20-40 min). To test for different concentrations of  $\text{Ca}^{2+}$  against the background of interfering ions, at 30 minute intervals increasing volumes of  $10^{-1}$  M  $\text{CaCl}_2$  solution were sequentially added by pipette to achieve 10-fold increments in  $\text{Ca}^{2+}$  concentration from  $10^{-8}$  to  $10^{-2}$  M while continuously stirring (low speed) and monitoring the voltage at the sense terminals. The pH of the solution was not modified through the addition of acidic/basic solutions during these experiments. For

1 comparison the same experiments were performed with an unfunctionalized (bare  
2 gate) device.  
3

## 4 **Results and discussion**

5  
6  
7 Figure 3 shows a plot of the sensor output as a function of time as  $\text{Ca}^{2+}$  was  
8 increased in 10-fold increments from approximately  $10^{-8}$  M to  $10^{-2}$  M in 0.01M KCl  
9 solution. The device showed a clear response to the change in  $\text{Ca}^{2+}$  ions, even at  
10 concentrations as low as  $10^{-8}$  M. The reason for the drift and diminished response at  
11 the highest analyte concentration is unknown, but is likely due to secondary  
12 membrane effects such as Donnan exclusion failure [29]. Furthermore, the transient  
13 peaks observed in the sensor response, at the instant  $\text{Ca}^{2+}$  ion is added, may be  
14 caused by the disturbance resulting from the introduction of the additional aqueous  
15 solution, containing the ions of interest, into the measurement beaker. For the long-  
16 term and practical application of these sensors, a different methodology, such as  
17 micro-fluidics, could be used for the introduction of ionic solutions.

34 **Figure 3:** Response of GaN/AlGaIn/GaN devices with calcium selective membrane  
35 to changes in  $\text{Ca}^{2+}$  concentration in a 0.01M KCl ionic buffer solution. Plot shows  
36 sensor output (voltage across sense terminals for constant forcing current of 100  $\mu\text{A}$ )  
37 over a time period during which the  $\text{Ca}^{2+}$  concentration was raised from  $10^{-8}$  M to  $10^{-2}$   
38 M by consecutive additions of  $\text{CaCl}_2$  solution.

43  
44  
45

46 Figure 4 shows the sensor output vs  $\text{Ca}^{2+}$  concentration in 0.01 M KCl buffer solution  
47 for four consecutive exposure sequences at 3-day intervals. The results show minor  
48 variability and this is likely due to differing testing conditions (i.e. temperature, light  
49 exposure, etc.). Despite this, after accounting for a different offset value for each  
50 run, the sensors show a consistent response in a 0.01 M KCl solution over a period  
51 of 2 weeks, with a lower detection limit as low as  $10^{-8}$ M in some runs (1<sup>st</sup> and 3<sup>rd</sup>),  
52

65

1 and a linear response range between  $10^{-7}$ M -  $10^{-2}$ M, in KCl solution. The worst case  
2 (run 4) detection limit was approximately  $10^{-7}$  M. All detection limits were determined  
3 using the IUPAC definition of detection limit for electrochemical sensors [13]. The  
4 detection limits for these sensors are, with the exception of run 4, at least one order  
5 of magnitude lower than those reported for ISFET or conventional ISE technologies  
6 as previously referenced [10, 11], and are also the best reported for reference  
7 electrode free technology [9]. While it is true that detection limits as low as  $10^{-10}$  M  
8 have been reported for ISE technologies [13], this only occurs when the analyte  
9 concentration in the inner solution is moderated between the classical and super-  
10 Nernstian responses. However, controlling analyte concentration in an inner solution  
11 is inconvenient for on-field *in situ* operation. Finally, although not shown here, the  
12 unfunctionalised devices without PVC membrane coating showed a negligible  
13 response to  $\text{Ca}^{2+}$  ions, as expected.

31 **Figure 4:** Plot of step change ( $\Delta V = V_{\text{before Ca}^{2+} \text{ added}} - V_{\text{after Ca}^{2+} \text{ added}}$ ) versus  $\text{Ca}^{2+}$   
32 concentration in a 0.01 M KCl interfering ion solution for GaN/AlGaN/GaN devices  
33 with  $\text{Ca}^{2+}$  selective membrane, for four separate experiments with intervals of 4 days  
34 between each experiment. An error of approximately 3 % is determined based on  
35 three times the noise level seen in the time vs. voltage series for each set of  
36 experiments.

46 The method to obtain apparent changes in the applied gate voltage and ion  
47 selectivity coefficients in this work has been previously published [22, 24] and is  
48 reiterated here for the specific devices under study. Quantitative determination of the  
49 selectivity coefficients for these interfering ions requires fitting the Nikolskii-Eisenman  
50 equation to the equilibrium sensor response values; but the apparent gate voltage

1 change due to ion sorption into the membrane is required before this equation can  
2 be used.  
3

4 The drain-source expression for field effect transistors operating in the non-saturated  
5 triode region can be described using:  
6  
7

$$8 \quad I_D = \mu C \frac{W}{L} V_{SD} \left( (V_G - V_T) - \frac{1}{2} V_{SD} \right) \quad (1)$$

9  
10 where  $I_D$  is the drain current,  $\mu$  is the channel electron mobility,  $C$  is capacitance  
11 density of the gate,  $W$  is channel width,  $L$  is channel length,  $V_{SD}$  is source-drain  
12 voltage,  $V_G$  is gate voltage and  $V_T$  is threshold voltage. When drain voltages are very  
13 small ( $V_{SD} \ll V_G - V_T$ ), Eq. (1) is approximated as:  
14  
15

$$16 \quad I_D \approx \mu C \frac{W}{L} V_{SD} (V_G - V_T) \quad (2)$$

17  
18 For this study, the current was selected to ensure operation of the device within the  
19 linear regime (triode region).  
20  
21

22 For ISFETs operated with a reference electrode,  $I_D$  and  $V_{SD}$  are maintained at  
23 constant values during sensing measurements. A feedback loop adjusts the potential  
24 applied to the reference electrode as a solution-gate for the transistor when the  
25 trans-membrane potential varies with ion concentration. This applied potential is the  
26 Nernstian response that is typically the output of an ISFET device. For our sensors,  
27 operated without a reference electrode, the device is effectively operated as a  
28 resistor and the source-drain potential,  $V_{SD}$ , is adjusted using a feedback loop to  
29 keep the drain current,  $I_D$ , constant. Changes in  $V_{SD}$ , due to exposure of the sensor  
30 to different ion concentrations, correspond to changes in channel conductivity and  
31 therefore in effective gate bias. Rearranging Eq. (2) shows that when drain current is  
32 constant (and selected for the linear regime), the conductance of the sensing layer is  
33 proportional to the gate voltage. For the particular structure used in this work (mole

fraction of  $x=0.25$  for the AlGaN layer and dielectric thicknesses of  $d_{AlGaN}=15.5\text{nm}$  and  $d_{GaN}=2\text{nm}$ ) this relationship between change in the sensing layer conductivity and change in apparent gate voltage is given by:

$$V_G - V_T(mV) = \frac{G_{sense}(\mu S)}{0.687(mF/Vs)} \quad (3)$$

It should be noted that, due to electrical contact passivation with SU-8, the measured source-drain voltage (used to determine conductivity) is affected by parasitic current channels. This was not the case for the previous device design for the nitrate and mercury sensors. In this work the channel conductivity was therefore extracted from total conductivity by modelling the parasitic regions as a shunt and access resistance [30].

A linear relationship exists between the conductivity of the transistor channel and the gate voltage for the transistor device biased to operate in the linear region and hence the equilibrium response data can be represented in terms of  $V_G - V_T$  by measuring the conductivity of the channel. For potentiometric sensors operated with a reference electrode, the relationship between gate voltage and potentiometric response is described by the Nikolskii-Eisenman equation:

$$V_G - V_T = E_0 - R \log(a_{calcium} + K \cdot a_{ion\ buffer}^{z_{calcium}/z_{ion\ buffer}}) \quad (4)$$

where  $E_0$  is a device constant,  $R$  is potentiometric response slope,  $K$  is the selectivity coefficient,  $z_i$  the charge number and  $a$  is the activity coefficient. The expected Nernstian slope for divalent ions is  $29.7\text{ mV}$  per 10-fold change in ion concentration at room temperature. Therefore, the potentiometric response slope and the selectivity coefficients can be determined by fitting the data to Eq. 4.

Figure 5 shows the equilibrium sensor output as a function of  $\text{Ca}^{2+}$  concentration in solutions containing various interfering ions and selectivity coefficients are summarized in Table 1. These results show that  $\text{Na}^+$  and  $\text{K}^+$  are only weakly

1 interfering ions, while  $Mg^{2+}$  and  $Li^+$  ions affect the response much more significantly.  
2 The fitting parameters (response slope) are also given in Table 1 and show that a  
3 near-Nernstian response was obtained for KCl and NaCl. For  $MgCl_2$  and LiCl,  
4 significant interference was observed and the response is sub-Nernstian. This is due  
5 to relatively stronger binding characteristics of these interfering ions with the  
6 ionophore [30]. For KCl and NaCl as interfering ions, sensor characteristics showed  
7 calcium detection limits of well below  $10^{-7}$  M and a linear response range between  
8  $10^{-7}$  -  $10^{-2}$  M. However, for  $MgCl_2$  and LiCl, the detection limit increased significantly.  
9 The selectivity coefficients determined here are slightly poorer compared to values  
10 determined by Gehrig et al. using the same ionophore [27]. The reason for this  
11 might be attributed to differences in sensor design. Such limits and dynamic range  
12 are still relevant for various practical fields such as agriculture, industrial processes  
13 and biomedical applications and are the lowest detection limits reported both for  
14 ISEs in classical set-up and for any ISFET technology [10, 11], as well as for any  
15 reference electrode free operation of sensors for  $Ca^{2+}$  ions [9].

**Table 1:** Sensor performance in different ionic strength buffer solution. For KCl and  
NaCl, it is difficult to fit the data to Nikolskii-Eisenmann equation and in these cases,  
the estimate of the selectivity coefficient is determined based on the lower detection  
limit [31].

Ionic strength buffer solution	Selectivity coefficient log K	Selectivity coefficient log K (Ref.[27])	Response slope (mV/log <sub>10</sub> [Ca <sup>2+</sup> ])	Linear response range (M)	Lower detection limit (M)
KCl	~ -3	-7.5	26.4	10 <sup>-7</sup> -10 <sup>-2</sup>	10 <sup>-7</sup>
NaCl	~ -3	-5.9	27.1	10 <sup>-7</sup> -10 <sup>-2</sup>	10 <sup>-7</sup>
MgCl <sub>2</sub>	-3.6	-4.4	14.6	10 <sup>-5.5</sup> -10 <sup>-2</sup>	10 <sup>-6</sup>
LiCl	-2.2	-5.8	13.2	10 <sup>-5.5</sup> -10 <sup>-2</sup>	10 <sup>-6</sup>

**Conclusion:**

Detection of Ca<sup>2+</sup> ions by incorporation of an ion selective membrane onto an AlGaIn/GaN-based transistor device operated without the use of a reference electrode was demonstrated. For KCl and NaCl as interfering ions, sensor characteristics showed calcium detection limits of well below 10<sup>-7</sup> M (10<sup>-8</sup> M in the best case) and a linear response range between 10<sup>-7</sup> - 10<sup>-2</sup> M.

These are the lowest detection limits reported both for ISEs in classical set-up and for any ISFET technology [10, 11], as well as for any reference electrode free operation of sensors for Ca<sup>2+</sup> ions [9].

Device operation without requiring a reference electrode means that associated issues of stability, maintenance and short lifetimes associated with the reference electrodes are eliminated, and opens up opportunities for miniaturisation and system integration. Despite having slightly poorer selectivity coefficients compared to previous studies using the same ionophore, it is still possible that the membrane formulation could be optimised to achieve improved selectivity. Further studies of

1 this technology can be expanded by integrating an array of sensors with membranes  
2 of different composition onto a single chip to detect various analytes simultaneously.
